

Assignment #6

Hugo SALOU

Consider a formula φ with n variables. We can construct an oracle for φ by using swaps and NANDs (as any propositional formula can be transformed into an equivalent formula using only variables and NANDs in poly-time). Using ancillas, we can evaluate φ on some valuation b_1, \dots, b_n with

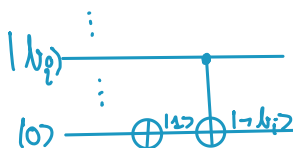

Evaluate
a subformula
 $b_i \text{ NAND } b_j$

In the above circuit, we implicitly assumed that $i < j$. This can be done as the NAND operation is symmetric (Same thing if ϕ 's partial result is "higher" than ψ 's).

To evaluate a subformula of the form $\phi \text{ NAND } \psi$, we use a very similar tactic but we place the Toffoli's controls on the two qubits responsible for ϕ 's and ψ 's partial result.

The only case that is somewhat ambiguous is $i = j$, but we can simply use a CNOT gate whose control is on $b_i = b_j$:

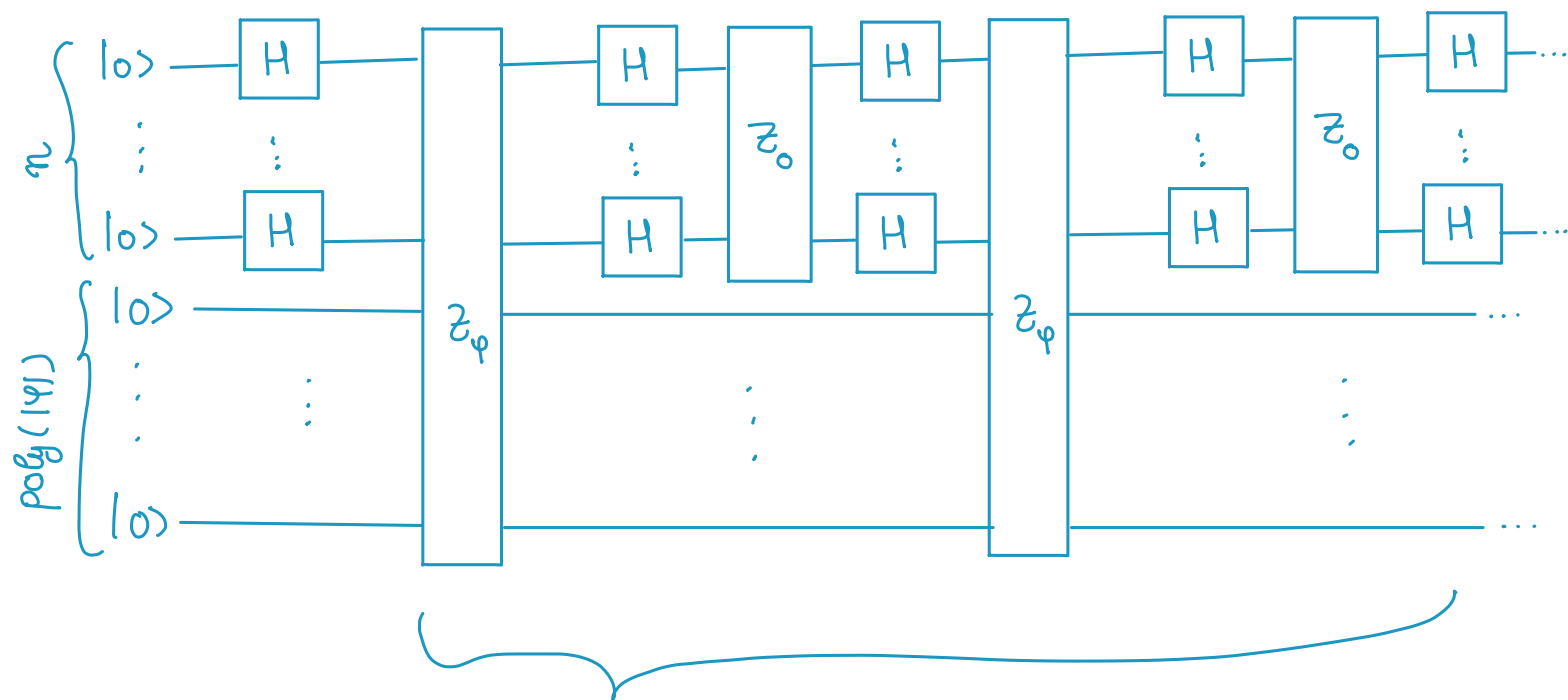

Using Tutorial #5's results, we can obtain a query oracle for evaluating φ :

$$Z_{\varphi} |b_1 \dots b_n\rangle |0^{\text{poly}(|\varphi|)}\rangle = (-1)^{\varphi} |b_1 \dots b_n\rangle |0^{\text{poly}(|\varphi|)}\rangle.$$

(Q1, part III of Tutorial #5).

We can thus apply Grover's algorithm to the n first inputs of Z_{φ} :

Repeat k times

As multiple valuations $(b_1^l, \dots, b_n^l)_{l \in [1, m]}$ can satisfy φ , we can run

Grover's algorithm for decreasing values of k : $k = 2^n / 2^{\text{iter}} = 2^{n - \text{iter}}$ where iter is the number of iterations of (not in) Grover's algorithm.

With high probability, we have $k = O(\sqrt{2^n / \ell})$, thus we have

a circuit of size

$$O(k \cdot (\text{size}(u_\varphi) + \underbrace{\text{size}(z_0)}_{\substack{\leq \text{poly}(n) \\ \leq \text{poly}(|\varphi|)}})) = O(2^{n/2} \text{poly}(|\varphi|))$$
